ABSTRACT

Extraskelatal osteosarcoma is a rare mesenchymal malignancy arising in soft tissue that produces osteoid, neoplastic bone, or chondroid material without demonstrable attachments to bone or periosteum. We report an instructive case of extraskelatal osteosarcoma in a 42-year-old woman recognized following acute traumatic injury of her left thigh.

Introduction

Extraskelatal osteosarcoma (ESOS) is a rare malignant mesenchymal neoplasm that produces osteoid, located in the soft tissues without skeletal or periosteal attachment [1-5]. Its most common location is the soft tissues of the thigh (46%), followed by the upper extremity (20%) and the retroperitoneum (17%); but can occur in any part of the body [3, 6-11]. Almost 700 cases of ESOS have been reported in English literature; and a history of prior trauma is present in 12.5% of patients [1, 8, 12, 13]. Here, we report a 42-year-old woman who presented with clinical, imaging and pathological features of osteoblastic extraskelatal osteosarcoma after a 3-month-episode of trauma of her left thigh.

Case Report

A 42-year-old woman, previously healthy, was initially treated in a private Clinic for a 1-month-trauma to her proximal left thigh (pedestrian stuck by a motorcycle while crossing the road). Her evaluation was suspicious for posttraumatic hematoma and was asked to return for follow up if symptoms were not improved. She returned 3 months later with a painless, rapidly enlarging mass at the posterior surface of the

proximal left thigh. Due to this unusual presentation, she was thereafter transferred to our Clinic. On her arrival, she was healthy appearing with left limping and right-sided sitting position. There was a non-tender, well-circumscribed, fixed, elastic-firm soft tissue mass measuring 30 cm x 24 cm and adhering to the deep fascia with shiny skin arising from the posterior surface of the left thigh up to the gluteal fold. The diameter of the thigh at the top of the mass (5 cm from the distal gluteal fold) was 80 cm opposed to 62 cm on the contralateral thigh (Figure 1). The left knee was free with the range of motion (ROM) of 0/0/130°; but the flexion of the left hip was limited to 100°. The rest of the clinical examination was unremarkable.

Plain radiographs of the left thigh showed a large deep-seated soft tissue mass with marked calcifications in a radial pattern and without apparent bone involvement. The complementary Computed Tomography (CT) scan revealed a significant mixed solid and cystic mass within the muscles of the posterior compartment of the left thigh with multiple nodules and septations. The mass measured 22 cm x 15 cm x 14 cm with necrotic centers (35 per 10 high-power fields), and was vascularized by a branch of the left deep femoral artery. No skeletal involvement was visualized (Figure 2).

Figure 1: Clinical aspect of the tumor after 3 months of onset. It was a well-circumscribed, fixed, elastic-firm soft tissue mass adhering to the deep fascia with shiny skin and arising from the posterior surface of the left thigh up to the gluteal fold. It measured 30 cm x 24 cm.

Figure 2: CT scan of the left thigh showing a significant deep-seated mixed solid and cystic mass within the muscle of the posterior compartment measuring 22 cm x 15 cm x 14 cm. There are tiny focal areas of ossification, which correspond with osteoid produced by the tumor and metallic foreign bodies are from prior trauma. No skeletal involvement was visualized.

She underwent Magnetic Resonance Imaging (MRI) which showed a large marginated, multilobulated, heterogeneous mass of mixed intensity signal occupying the posterior compartment of the thigh measuring 15.64 cm x 13.07 cm axially and 26 cm x 11 cm coronally. It was a burgeoning mass with necrotic, fleshy and hemorrhagic components. There was no bone contact nor intraosseous invasion (Figure 3). Furthermore, her chest CT scan revealed the development of multiple large pulmonary masses, consistent with ‘cannonball’ metastasis. The largest was located in the right lung and measured 16.7 x 17.0 cm (Figure 4). Due to these findings, the consent was made with the patient to undergo wide margin surgical resection of the mass with subsequent pathology and immunohistochemistry analysis. Pathology results showed on gross pathology; tissue fragments of whitish appearance and fibrous locally myxoid (Figure 5).

Figure 3: Sagittal and axial T2-weighted MRI showing a large marginated, multilobulated, heterogeneous mass of mixed intensity signal occupying the posterior compartment of the thigh measuring axially 15.64 cm x 13.07 cm and coronally 26 cm x 11 cm.

Figure 4: Chest CT scan showing the development of multiple pulmonary masses with the largest measuring 16.7 x 17.0 in the right lung, consistent with ‘cannonball’ metastasis.

Figure 5: Gross surgical specimen cut section.

The micro-pathology found anaplastic spindle cell proliferation, cytological atypia, malignant chondroid areas, extensive areas of necrosis, mitotic activity and atypical mitotic figures with the presence of osteoid matrix formed by the neoplastic cells (Figure 6). Immunostaining for S100 protein was negative. The pathology results of the excision were significant for osteoblastic osteosarcoma. In the absence of bony involvement on imaging, we concluded to the diagnosis of osteoblastic extraskeletal osteosarcoma. Chemotherapy has been recommended; and the pre-therapeutic assessment has been carried out. The established chemotherapy protocol was a multiagent chemotherapy comprising Doxorubicin, Methotrexate and Cisplatin. The first treatment

was done at third month (M3) postoperatively. The follow up was marked by a local recurrence with a budding wound at the surgical site after 45 days (D45) post excision. The patient died at the ninth month (M9) after the onset of the first symptoms which correspond to the fifth month (M5) post diagnosis of extraskelatal osteosarcoma.

Figure 6: Different high power histological sections showing: **a)** Pleomorphic malignant cells with extracellular matrix production (stain, hematoxylin and eosin; original magnification, 200x); **b)** Anaplastic spindle cell proliferation with the presence of osteoid matrix formed by the neoplastic cells; **c)** Polyhedral cells with cytological atypia, malignant chondroid areas, extensive areas of necrosis, mitotic activity and atypical mitotic figures; **d)** The tumor infiltrating the muscle.

Discussion

Extraskelatal osteosarcoma (ESOS) is a high-grade malignant mesenchymal soft tissue neoplasm composed of neoplastic cells (osteoblastic, chondroblastic and fibroblastic) that produce osteoid, neoplastic bone or chondroid matrix and has a clinically aggressive course [3, 5, 14, 15]. For a lesion to be defined as extraskelatal osteosarcoma, it must arise in the soft tissue and not attached to bone or periosteum, have a uniform sarcomatous pattern, and produce osteoid and/or cartilage matrix [5, 16-19]. Since it was originally described by Wilson in 1941 and further defined by Allan in 1971, less than 700 cases have been reported in the current modern English literature and this underlines its rarity [1, 3, 12, 13]. ESOS accounts for 1% of all soft tissue sarcomas and 4% of osteogenic osteosarcomas [3, 7, 18, 20, 21].

Known predisposing factors for development of ESOS include middle aged or elderly patients, involvement of lower extremities, a history of radiation and a controversial link to traumatic events [2-13]. ESOS is a tumor primarily of older age (mean age: 47.5 to 61 years) and male predominance (male to female ratio: 1.9:1) [2, 5, 7-22]. In a large series treated at a single institution, Wang *et al.* have found that 63% patients with ESOS were over 50 years [15]. However, pediatric patients have also been reported, for example, in the soft thigh tissue of a 6-year-old boy and a high-grade ESOS in the breast of a 16-year-old female [18, 23, 24]. Most extraskelatal osteosarcomas are deep seated; <10% are superficial, originating in the dermis or subcutis. The most common location is the lower extremity (75%; thigh and buttock), followed by the upper extremity (15-23%, shoulder girdle), and the retroperitoneum (17%); but can occur in any part of the body [3, 6-11]. Approximately 4-13% of reported cases occur secondary to radiation therapy, with the therapy taking place 2-40 years prior to presentation [6, 8-25]. Multiple

cases of ESOS occurrences have been recognized after traumatic events. The time frame from trauma to diagnosis ranged from 10 months to 12 years and others diagnosed 25 and 36 years after the inciting traumatic event [1, 12, 21, 26, 27]. In our case, we have a 42-year-old woman (middle aged) with a deep seated painless tumor, episode of recent trauma (pedestrian stuck) and involvement of lower extremity (posterior surface of the left proximal thigh). No history of radiation exposure. In reported traumatic cases, the questionably development of ESOS has been primarily seen years later, which is in stark contrast to our patient's rapid development in only 3 months.

Symptoms usually include a slowly growing painless mass in an extremity [5, 6-20]. In trauma patients, these symptoms often mask the ESOS diagnosis and are assumed to be hematoma or other traumatic diagnosis [21, 26, 27]. Radiographs may show a soft tissue mass with variable amounts of mineralization, and a lack of skeletal involvement. No calcification is seen in approximately 50% of lesions [12]. CT scans demonstrate a soft tissue mass often displacing fat planes, with variable degrees of calcification/ossification. MRI shows a soft tissue mass with the non-mineralized areas showing nonspecific intermediate to low signal intensity on T1 weighted images, and high signal intensity on T2 weighted images reflecting tumor edema. Foci of hemorrhage and necrosis are also common. The tumors often appear well circumscribed and pseudoencapsulated, or infiltrative into the surrounding soft tissues. Extraskelatal osteosarcomas are usually large at diagnosis, typically averaging 9 cm in diameter. Microscopically, by definition, they display at least some osteoid and often there are variable amounts of bone or cartilage, often blending into a high-grade sarcomatous stroma [1, 6-21]. All these features were found in our patient and the tumor was osteoblastic extraskelatal osteosarcoma in nature measuring 30 cm x 24 cm in diameters.

Wide margin surgical resection is the mainstay of treatment for extraskelatal osteosarcoma [4, 5-28]. Resection can be with amputation of limb salvage surgery if microscopically negative margins can be achieved [29, 30]. Treatment decisions regarding adjuvant chemotherapy or radiation therapy for ESOS should be individualized, based on the assessment of relative risk factors. However, the effectiveness of radiation and chemotherapy remains uncertain owing to conflicting results in previous reports [31]. More recent groups that have used multiagent chemotherapy and wide resection during surgical procedures have described overall survival rates of 66 to 77%, similar to skeletal osteosarcoma and there was a trend towards increased length of survival in patients who received chemotherapy compared to those who did not (16.4 months versus 9.3 months, $p=0.16$) [14-22]. Given the high grade malignant tumor and poor prognosis, aggressive treatment with preoperative radiation therapy and surgical resection for local tumor control, and (neo-) adjuvant multiagent chemotherapy to improve survival are current treatments of choice for the patients with extraskelatal osteosarcomas. Aggressive thoracotomy and resection of the pulmonary metastases may be necessary in patients with lung metastases. Our patient underwent wide margin surgical resection of the tumor and multiagent adjuvant chemotherapy (Doxorubicin, Methotrexate and Cisplatin).

The prognosis of the patients with extraskelatal osteosarcoma is poor; the 5-year survival ranges from 10-46%. More than 50% of the patients

experience multiple local recurrences with wound-healing complications and distal metastases. Distal metastases are usually to the lungs (>80%), followed by the regional lymph nodes (4-29%), bone (8-19%), adrenal gland (<5%), brain, liver and skin [3, 5, 15-18]. Reported adverse prognostic factors include metastatic disease at presentation, large tumor size, and inability to achieve complete surgical resection [22]. Tumor size has also been reported as an important prognostic factor. In the study of Bane *et al.*, comparing patients with a tumor size of <5 cm to size >5 cm, tumor size was an important predictive value of patient survival ($p < 0.001$). Only one tumor related death occurred in the <5 cm group out of 7 patients, whereas in comparison to 14 deaths in a >5 cm population of 16, at time of study production [6]. To add further evidence to the significance of tumor size in ESOS survival, Terence T. Sio *et al.* compared tumor size, with their variable of study being 10 cm. According to their published data, a 5-year-survival rate of 76% was appreciated in patients with a tumor size <10 cm, in comparison to 36% 5-year-survival rate in those patients with tumor size of >10 cm ($p=0.002$) [18]. Our patient had a significantly large tumor, measuring 30 cm x 24 cm at time of surgical excision. She had bilateral lung metastasis. The follow up was marked by a local recurrence with a budding wound at the surgical site after 45 days post-surgery, and unfortunately died 5 months after the diagnosis of extraskelatal osteosarcoma was made despite multiagent neo-adjuvant chemotherapy.

Conclusion

Through extensive review of the modern English literature, there is no question that extraskelatal osteosarcoma is a rare medical entity. Easy misinterpretation of what appears to be obvious traumatic injury, can lead to delays in accurate diagnosis and appropriate management of ESOS. Its diagnosis is made by a thoroughly clinical examination and confirmed by both imaging and pathology. Wide margin surgical resection is the mainstay of treatment. Adjuvant chemotherapy and/or preoperative radiation therapy may be useful. The case presented here displays particular attention to clinicians to regularly practice strict follow up visits after traumatic events to the lower extremities in middle aged and elderly patients.

Ethical Consideration

Written informed consent was obtained from the patient's husband, given her death during production for publication of this paper. Ethical approval to report this case was obtained from the Ethical Board of Tamba Counda Hospital, Senegal on 26th November 2018.

Conflicts of Interest

None.
